### Abstract

Phenomenon of genotype by environment interaction was able to influence the stability performance of cocoa resistance to Phytophthora pod rot (PPR). This research had an objective to evaluate the effect of genotype by environment interaction on resistance of cocoa hybrids to PPR. The tested hybrids were F<sub>1</sub> crosses between selected clones of TSH 858, Sulawesi 1, Sulawesi 2, NIC 7, ICS 13, KEE 2 and KW 165. There were 14 tested hybrids and an open pollinated hybrid of ICS 60 x Sca 12 was used as control in multilocation trials at four different agroclimatic locations, namely Jatirono Estate ((highland-wet climate), Kalitelepak Estate (lowland-wet climate), Kaliwining Experimental Station (low land-dry climate) and Sumber Asin Experimental Station (highland-dry climate). Trials were established in the randomized complete block design with four replications. Resistance to PPR were evaluated based on the percentage of infected pod for the years during wet climate of 2010 in Jatirono, Kalitelepak and Kaliwining followed in dry climate of 2011–2015 in Kaliwining and Sumber Asin. Variance of data were analyzed for detecting the effect of genotype by environment interaction (GxE) then visualized with a graph of genotype main effect and genotype by environment interaction (a graph of GGE) biplot. There was consistently no interaction effect between hybrid and location to PPR incidence which was affected by single factor of hybrid, year, location and interaction between year and location. The effect of year indicated yearly change of weather was more important to PPR incidence than location difference. A graph of GGE biplot indicated a stable performance of the tested hybrids among locations.

### INTRODUCTION

Phytophthora pod rot (PPR) caused by the infection of *Phytophthora palmivora* is the most serious diseases on cocoa in Indonesia, especially in location situated with high humidity (wet climate). Yield losses due to PPR was estimated up to 20–30% and might result in secondary disease of stem cancer

which cause plant die up to 10% (Guest *et al.*, 2007). Controlling the diseases has been recommended by integrated approach using resistant planting materials, biological or chemical agents and cultural practices (Acebo-Guerrero *et al.*, 2011). The approach of cultural practices was aimed to stabilize environmental condition which is less favorable for the diseases to grow. Resistant planting

materials should be more effective and durable in addressing the diseases than other approaches but it need a long time process and need more fund for replanting existing farm. Furthermore, strategy on controlling PPR should be directed in short term or long term approaches depend on the level of disease severity.

There are some recommended cocoa planting materials which are resistant to PPR for addressing the diseases such as ICCRI 03, ICCRI 04 (Susilo *et al.*, 2013) and hybrids generated from resistant clones of Sca 6 and Sca 12 (Iswanto & Winarno, 1992). The genetic factor contributes important resistant expression, however, environmental effect also play significant role on the resistance due to the effect of genotype by environment interaction. It was reported that broadsense heritability of PPR resistance was in moderate category (Susilo *et al.*, 2002; Purwantara *et al.*, 2015) that means the contribution of environment factors was important in affecting the resistance. Air humidity is of the most important environmental condition which directly affecting the growth of *P. palmivora* (Guest, 2007) that yearly environmental change is able to influence the dynamic of PPR resistance. Furthermore, more susceptible plants would be more sensitive to environmental change than resistant ones (Purwantara *et al.*, 2015). This study also reported that intensity of PPR incidence increased higher at the susceptible cocoa from <20% during dry season to 46% during wet season. It is important to understand the phenomenon of genotype by environment interaction on new cocoa varieties to maximize their utilization for controlling PPR.

Breeding for cocoa resistance to PPR were carried out simultaneously in order to improve genetic background of resistant planting materials in Indonesia. The main goal is to develop multigenic of the resistance

of high yielding genotype to main diseases such as PPR and *vascular-streak dieback* (VSD, *Ceratobasidium theobromae*). Gutiérrez *et al.* (2015) reported the Pound's strategies on cocoa breeding resistance to pest and diseases in Trinidad by using intrecrossing between the wild germplasm and cultivated germplasm to accumulate desirable genes for resistance. Success story on selection the multigenic resistant genotypes on cocoa was reported. The cocoa clone of Sca 6 which having resistance to PPR, VSD and *Helopeltis* sp. (Susilo *et al.*, 2009) and of the local clones from North Luwu South Sulawesi of MCC 02 which having resistance to VSD, PPR and cocoa pod borer (CPB) (Susilo *et al.*, 2015) both of which may inspiring breeding objectives on developing multigenic resistant on cocoa genotypes to main pests and diseases. Breeding for cocoa resistance to PPR and VSD has been carried out by inter-crossing the selected parental clones which having differences on the disease resistant background and cross compatibility (Susilo *et al.*, 2011). Hybrids of the crosses had been tested in multilocation trials wherein specified with the differences on agro-climatic condition to assess stability performance on PPR resistance referring to resistant hybrid of ICS 60 x Sca 12. It was unknown the effect of genetic by environment interaction (G x E) on PPR resistance of the tested hybrid that would be very useful information on developing PPR resistant hybrids as cocoa planting materials. This research was carried out in order to observe the effect of G x E on PPR resistance of some promising hybrids through multilocation trials for releasing the selected hybrids as resistant planting materials. This paper discuss results of the analysis that performing effect of single factors and their interaction of genetic, location and year on PPR resistance as the basis information for utilizing the selected hybrids for farmers.

## MATERIALS AND METHODS

Genetic materials for multilocation trials were the crosses hybrid between 7 selected clones using factorial design as was reported by Susilo (2011). Trials were established in the randomized complete block design with 4 blocks as replication. There were tested 14 hybrids ( $F_1$  and reciprocal crosses) and an open pollinated hybrid of ICS 60 x Sca 12 was used as control. Seedlings of the tested hybrids were derived by hand pollination crossing system at Kaliwining Experimental Station of Indonesian Coffee and Cocoa Research Institute (ICCRI) in Jember wherein situated in 45 m above sea level (asl.) and D type of climate according Schmidt-Ferguson classification.

Multilocation trials were carried out at four different agroclimatic locations, namely Kaliwining Exp. Station of ICCRI in Jember (low land - dry climate), Sumber Asin Experiment Station of ICCRI in Malang (high land-dry climate), Jatirono Estate in Banyuwangi (high land-wet climate) and Kalitelepak Estate in Banyuwangi (low land-wet climate). Trials used different number of sample trees per plot as limited land area, such as 16 trees in Kaliwining, 28 trees in Sumber Asin, 24 trees in Jatirono and 20 trees in Kalitelepak. The trees were planted in 2002/2003 and maintained according to good agricultural practices in planting distance of 3 m x 3 m under shade trees of lamtoro (*Leucaena glauca*), coconut (*Cocos nucifera*) and *Glyricideae* sp.

Evaluation the resistance to PPR was carried out by assessing the number of infected pod per plot basis in monthly interval during the year of time assessment. The assessment were conducted during wet climate of 2010 wherein situated with wet condition due to high rainfall all the year that supporting optimal growth of *Phytophthora* fungus in three locations of Kalitelepak, Jatirono and

Kaliwining then the data were classified derived during wet climate. Further assessments were followed in Kaliwining and Sumber Asin as the representative dry area during the year of 2011–2015 then the data were classified derived during dry climate.

The recorded data were performed to the combined analysis of variance to investigate the effect of genotype (hybrid), location, years and their interaction. Means were differentiated by Duncan multiple range test (DMRT) at 95% of significant level. Interpretation of genotype by environment interaction was also supported by a graph of GGE biplot (genotype main effect and genotype by environment interaction) refer to Yan & Kang (2003).

## RESULTS AND DISCUSSION

Results of combined-analysis of variance for PPR intensity showed significant effect of hybrid, year and interaction between hybrid and year but there was no significant effect of the interaction between hybrid and location (Table 1 and 2). Data recorded in 2010 showed that wet condition in the field due to heavy rain during all the year which was favorable for PPR growth, maximally influenced field infection of PPR to the plant. Therefore, it could be interpreted that the resistance of tested hybrids to PPR was not just affected by genetic factor but also by yearly environmental change due to significant effect of year to PPR intensity. The micro-climate change was mostly affected by annual rainfalls that influence air humidity in the field. There were consistently no significant effect of the interaction between hybrid and location to PPR intensity indicating that the strains of *P. palmivora* were very similar in their pathogenicity between locations that effected in no difference on PPR incidence. This was supported by previous report that

genetic diversity of *P. palmivora* was low (Purwantara & Umayah, 2010; Saul-Maora *et al.*, 2016; Surujdeo-Maharaj *et al.*, 2016). The different location effect was influenced by climate differences which mostly divided into wet and dry.

Intensity of PPR incidence was significantly various among tested hybrids (Table 3) performing any difference in their resistance. Mean of PPR incidence intensity of these hybrids recorded in wet climate of 2010 was varied between 35.7–55.7% which was higher than in dry climate of 2011–2015 between 17.7–24.9%. In general, intensity of PPR incidence was two times higher in wet climate of 2010 (43.98%) than in dry climate of 2011–2015 (20.85%). The high PPR intensity indicate highest level of PPR susceptibility of the tested hybrids was similar to the previous report by Purwantara *et al.* (2015) which showed the highest level of PPR intensity on susceptible clones was 46%. Others report by McMahon *et al.* (2010) supported this result which classified PPR resistance in four categories, which were resistant (<15%), moderate resistant (15–24%), moderate susceptible (25–34%) and susceptible (>34%). Referring to this classification therefore the resistance of tested hybrid to PPR was moderate resistant in dry climate and susceptible in wet climate.

These tested hybrids which having lower intensity of PPR incidence can be supposed to perform better resistance to *P. palmivora*. Suhendy *et al.* (2004) reported that the resistant clones of Sca 12 and KEE 2 have good combining ability for PPR resistance therefore hybrids generated by those resistant clones would be more resistant on the contrary this results indicate the tested hybrids inherited by using KEE 2 both as male or female performed less resistance to PPR than hybrids generated by susceptible clones such as TSH 858 and Sulawesi 1 (Table 4). This result confirms that KEE 2's combining ability for PPR resistance may be less compatible to the parental clones used in this study. The inheritance of PPR resistance was reported as additive and polygenic (Flamet *et al.*, 2001 *cit.* Guest, 2007) moreover Barreto *et al.* (2015) that reported the PPR resistance was inherited in oligogenic manner that breed for resistant genotypes to PPR should be inter-cross between resistant clones. de Cássia-Bahia *et al.* (2015) also confirmed this phenomenon on PPR resistance inheritance in which to breed PPR resistance hybrids were done by crossing between both resistant parental clones of Sca 6 and Catango.

This results consistently performed no significant effect of the interaction between hybrids and location to PPR resistance assessed

Table 4. Intensity of PPR incidence (%) of F<sub>1</sub> hybrids generated using the same clones both as male or female evaluated during wet climate of 2010

Clone	Intensity of PPR incidence (%) as maternal effect	Intensity of PPR incidence (%) as paternal effect
TSH 858	47.80	43.16
Sulawesi 1	40.17	47.23
KEE 2	48.15	45.73

at two different environmental conditions (wet and dry climate) (Table 2 & 3). Furthermore, genetic expression of the tested hybrids for PPR resistance were stable among locations as the differences on PPR resistance were due to micro-environment change and not affected by pathogenic differences of the fungus. In this case, air humidity was the environmental conditions most favoring for the fungus growth. Graph of GGE biplot visualize stability performance of the tested hybrids, in which most of the hybrids that were assessed during wet climate closely

positioned at the axis point indicating their stable performance among locations. Therefore, differences in intensity of PPR incidence among hybrids would depend on micro-environment change such as air humidity which supported the epidemic rather than plant resistance or pathogenicity of the fungus as the fungus relativeness were quite similar (Purwantara & Umayah, 2010).

GGE biplot (Figure 1A) visualize the differences of PPR intensity among locations where in Kaliwining situated in dry climate performed high intensity of PPR

Note : HKW 1 (TSH 858 x KEE 2), HKW 2 (TSH 858 x Sulawesi 1), HKW 3 (TSH 858 x NIC 7), HKW 4 (TSH 858 x ICS 13), HKW 5 (KEE 2 x TSH 858), HKW 6 (KEE 2 x Sulawesi 1), HKW 7 (KEE 2 x NIC 7), HKW 8 (KEE 2 x ICS 13), HKW 9 (Sulawesi 1 x KEE 2), HKW 10 (Sulawesi 1 x TSH 858), HKW 11 (Sulawesi 1 x NIC 7), HKW 12 (Sulawesi 1 x ICS 13), HKW 13 (Sulawesi 2 x KEE 2), HKW 14 (KW 165 x KEE 2) and control (open pollination ICS 60 x Sea 12). KWN 20xx = Kaliwining 20xx ; SA 20xx = Sumber Asin 20xx

Figure 1. GGE biplot of intensity of PPR incidence of the tested hybrids evaluated during wet climate of 2010 in three locations (A) and followed at dry climate of 2011-2015 in two locations (B)

incidences during wet climate of 2010. This result confirmed that micro-environment significantly affected PPR growth that environmental change of dry area (in which performed by Kaliwining location) possibly was better for favoring PPR intensity when air humidity very suitable for the fungus growth. McMahon *et al.* (2015) reported that the intensity of PPR incidence was significantly affected by the total of rainfall in monthly basis. However, further study reported by Surujdeo-Maharaj *et al.* (2016) informed that to complete its life cycle, *P. palmivora* also needed dry condition for spore dispersal and infection process. The zoospore growth also need a dry condition at least for 20–30 minutes (Guest, 2017). Furthermore the dry area would be more suitable for PPR growth when micro-environment condition match properly to the requirement condition of the PPR life cycle.

This result reconfirmed that performance of cocoa resistance to PPR in the field is not just affected by genetic of the plant but also by environmental condition of micro-environment change which would depend on the volume of rainfall and its distribution in monthly basis. Furthermore, the efforts to address PPR there should be able to combine integrated approach between resistant planting material with cultural practices to manage micro-environment in the location to be less favorable for PPR growth. This result indicate that the tested hybrids performed moderate resistance to PPR that development of the selected hybrid had to be combined integrally with other practical control especially cultural practices such as pruning heavy branches to reduce air humidity for suppressing PPR incidence.

## CONCLUSION

The intensity of PPR incidence on cocoa hybrids was affected by genetic factor and microenvironment change expressed by

the significant effect of year and there was no significant effect of the interaction between hybrids and locations. Mean differences of the intensity of PPR incidence among tested hybrids indicated moderate resistance to PPR in which the resistance would be affected by genetic effect and micro-environment change year by year but not affected by the specified locations.

## ACKNOWLEDGEMENT

The authors wish to thank Director of ICCRI for his permission on publishing this paper. We wish also to thank the managers of Kalitelepak Estate and Jatirono Estate of PTPN XII for their support in the facilitation of the multilocation trials. The success on implementing this research was also supported by the head of Kaliwining Experimental Station and Sumber Asin Experimental Station of ICCRI and the technicians of Plant Breeding Laboratory of ICCRI, especially thanks to Rudi Hartoyo and Sukarmin for their technical assistance.
